Introduction: The leading hypothesis for the origin of the Moon is the giant impact model, which grew out
of the post-Apollo science community [1]. The hypothesis was able to explain the high E-M system angular
momentum, the small lunar core, and consistent with the idea that the early Moon melted substantially.
The standard hypothesis requires that the Moon be made entirely from the impactor, strangely at odds with
the nearly identical O isotopic composition of the Earth and Moon, compositions that might be expected to be
different if Moon came from a distinct impactor [2]. Subsequent geochemical research has highlighted the
similarity of both geochemical and isotopic composition of the Earth and Moon [3], and measured small but
significant amounts of volatiles in lunar glassy materials [4], both of which are seemingly at odds with the
standard giant impact model. Here we focus on key geochemical measurements and spacecraft observations
that have prompted a healthy re-evaluation of the giant impact model, provide an overview of physical models
that are either newly proposed or slightly revised from previous ideas, to explain the new datasets.

Isotopic measurements Si, Mg, K, O, Fe, Ti, Cr, W, Mo, Ru: Many isotopic measurements of lunar and
terrestrial materials have revealed nearly identical values for the two bodies. Although for some isotopic
systems the inner solar system is quite uniform, there are some isotopic differences. For example a small
difference between lunar and terrestrial W and O [5,6] isotopic composition has been measured. The signifi-
cance of the similarities/differences is actively debated.

Volatiles: Lunar glasses contain measurable amounts of H, C, and S, which was surprising since many
previous studies had concluded that lunar materials are dry or even “bone dry” [4,7]. The rock record on
Earth does not extend back as far as that on the Moon, but it comes close with studies of zircons from
various Archean terranes such as the Jack Hills in Australia [8]. Such zircons have O isotopic compositions
indicating influence of water at the surface of the Earth, suggesting water was delivered early in Earth’s history,
and that the early Earth-Moon system may have contained more volatiles than previously thought. New
LRO measurements of volatiles at the lunar surface has also prompted re-evaluation of the origin and abundance
of lunar volatiles [9].

Response to new data: These new geochemical data, especially the isotopic data – have forced the is-
sue of why the Moon is not different in composition from Earth, as apparently predicted by the standard
giant impact scenario. Various revised or new ideas have been proposed to explain the new data.

Exploration of planetary dynamics: If a spun up Earth was impacted, the material ejected is mostly from
Earth [10]; a drawback is that this hotter resulting disk may be at odds with a volatile-bearing Moon. In a hit
and run collision [11], impact geometry allows more of the Moon to originate from proto-Earth’s mantle, but
raises the question “where is the impactor now?”. Solutions involving orbital resonances and Trojan Moons
allow the Moon to be accreted from material originating from nearly the same region as that of Earth [12].

Exploration of disk dynamics: The dynamics and evolution of the circumterrestrial disk include many
unexplored aspects. Outcomes of recent modelling [13] indicate that silicate Earth material might mantle
impactor material in the lunar interior as the circumterrestrial disc collapses into the Moon. Alternatively,
isotopic equilibration between hot Earth and the lunar disk may explain the Earth-like Moon [14], but this
could make disk instabilities that make it unviable.

New ideas motivated by geochemical data: Late stochastic accretion, in which Earth and Moon get dif-
ferent amounts of late chondritic additions, was proposed to explain W differences [15]. Other geochemi-
cal and isotopic modelling indicate that inner solar system material is Earth-like; in that case O isotopes
are expected to be similar, and W can be explained by Monte Carlo simulations [3].

Each of these new or revised ideas has pros and cons, which will be evaluated. Attempts will be made
to propose tests that might help distinguish these models and test their viability, including geochemical, dy-
namic, and exploration-based data or measurements.
